

## FEATURES

- 170 MSPS maximum conversion rate
- 500 MHz programmable analog bandwidth
- 0.5 V to 1.0 V analog input range
- Less than 450 ps p-p PLL clock jitter at 170 MSPS
- 3.3 V power supply
- Full sync processing
- Sync detect for hot plugging
- 2:1 analog input mux
- 4:2:2 output format mode
- Midscale clamping
- Power-down mode
- Low power: <1 W typical at 170 MSPS

## APPLICATIONS

- RGB graphics processing
- LCD monitors and projectors
- Plasma display panels
- Scan converters
- Microdisplays
- Digital TV

## GENERAL DESCRIPTION

The **AD9888** is a complete 8-bit, 170 MSPS, monolithic analog interface optimized for capturing RGB graphics signals from personal computers and workstations. Its 170 MSPS encode rate capability and full-power analog bandwidth of 500 MHz supports resolutions of up to 1600 × 1200 (UXGA) at 75 Hz.

For ease of design and to minimize cost, the **AD9888** is a fully integrated interface solution for flat panel displays. The **AD9888** includes an analog interface that has a 170 MHz triple ADC with an internal 1.25 V reference phase-locked loop (PLL) to generate a pixel clock from HSYNC and COAST; midscale clamping; and programmable gain, offset, and clamp controls. The user provides only a 3.3 V power supply, analog input, and HSYNC and COAST signals. Three-state CMOS outputs can be powered from 2.5 V to 3.3 V.

The on-chip PLL of the **AD9888** generates a pixel clock from the HSYNC and COAST inputs. Pixel clock output frequencies

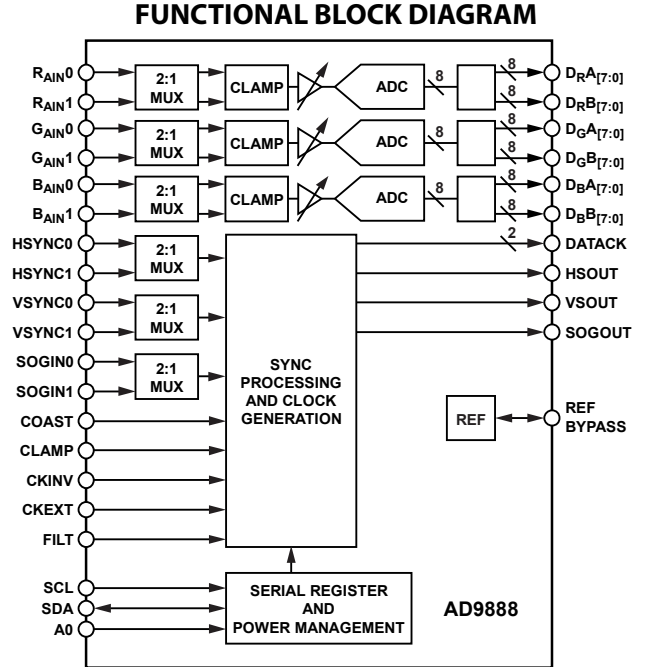

Figure 1.

range from 10 MHz to 170 MHz. PLL clock jitter is typically less than 450 ps p-p at 170 MSPS. When the COAST signal is presented, the PLL maintains its output frequency in the absence of HSYNC. A sampling phase adjustment is provided. Data, HSYNC, and clock output phase relationships are maintained. The PLL can be disabled, and an external clock input can be provided as the pixel clock. The **AD9888** also offers full sync processing for composite sync and sync-on-green applications.

A CLAMP signal is generated internally or can be provided by the user through the CLAMP input pin. This device is fully programmable via a 2-wire serial port.

Fabricated in an advanced CMOS process, the **AD9888** is provided in a space-saving, 128-lead, MQFP, surface-mount, plastic package and is specified over the 0°C to 70°C temperature range. The **AD9888** is also available in a Pb-free package.

## ABSOLUTE MAXIMUM RATINGS

Table 2.

Parameter	Rating
$V_D$	3.6 V
$V_{DD}$	3.6 V
Analog Inputs	$V_D$ to 0.0 V
REF BYPASS	$V_D$ to 0.0 V
Digital Inputs	5 V to 0.0 V
Digital Output Current	20 mA
Operating Temperature Range	-25°C to +85°C
Storage Temperature Range	-65°C to +150°C
Maximum Junction Temperature	150°C
Maximum Case Temperature	150°C

Stresses above those listed under Absolute Maximum Ratings may cause permanent damage to the device. This is a stress rating only; functional operation of the device at these or any other conditions above those indicated in the operational section of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect device reliability.

## EXPLANATION OF TEST LEVELS

- I. 100% production tested.
- II. 100% production tested at 25°C; sample tested at specified temperatures.
- III. Sample tested only.
- IV. Parameter is guaranteed by design and characterization testing.
- V. Parameter is a typical value only.
- VI. 100% production tested at 25°C; guaranteed by design and characterization testing.

## ESD CAUTION

**ESD (electrostatic discharge) sensitive device.** Charged devices and circuit boards can discharge without detection. Although this product features patented or proprietary protection circuitry, damage may occur on devices subjected to high energy ESD. Therefore, proper ESD precautions should be taken to avoid performance degradation or loss of functionality.

# PIN CONFIGURATION AND FUNCTION DESCRIPTIONS

Figure 3. Pin Configuration

Data Clock Output	DATA <sub>CK</sub>	Data Output Clock.	3.3 V CMOS	123
	DATA <sub>CK</sub>	Data Output Clock Complement.	3.3 V CMOS	124

Table 4. Pin Function Descriptions

Mnemonic	Description
Inputs	
R <sub>AIN0</sub>	Channel 0 Analog Input for Red.
G <sub>AIN0</sub>	Channel 0 Analog Input for Green.
B <sub>AIN0</sub>	Channel 0 Analog Input for Blue.
R <sub>AIN1</sub>	Channel 1 Analog Input for Red.
G <sub>AIN1</sub>	Channel 1 Analog Input for Green.
B <sub>AIN1</sub>	Channel 1 Analog Input for Blue.
	These high impedance inputs accept red, green, and blue channel graphics signals, respectively. The six channels are identical and can be used for any color; colors are assigned for convenient reference. They accommodate input signals ranging from 0.5 V to 1.0 V full scale. Signals should be ac-coupled to these pins to support clamp operation.
HSYNC0	Channel 0 Horizontal Sync Input.
HSYNC1	Channel 1 Horizontal Sync Input.
	These inputs receive a logic signal that establishes the horizontal timing reference and provides the frequency reference for pixel clock generation. The logic sense of this pin is controlled by the HSYNC input polarity control (Register 0x0E, Bit 6). Only the leading edge of HSYNC is used by the PLL. The trailing edge is used for clamp timing only. When the HSYNC input polarity control = 0, the falling edge of HSYNC is used. When the HSYNC polarity control = 1, the rising edge is active. The input includes a Schmitt trigger for noise immunity, with a nominal input threshold of 1.5 V.
VSYNC0	Channel 0 Vertical Sync Input.
VSYNC1	Channel 1 Vertical Sync Input.
	These are the inputs for vertical sync.
SOGIN0	Channel 0 Sync-on-Green Input.
SOGIN1	Channel 1 Sync-on-Green Input.
	These inputs are provided to assist in processing signals with embedded sync, typically on the green channel. These pins are connected to a high speed comparator with an internally generated, variable threshold level, which is nominally set to 0.15 V above the negative peak of the input signal. When connected to an ac-coupled graphics signal with embedded sync, these pins produce a noninverting digital output on SOGOUT. This output is usually a composite sync signal, containing both vertical and horizontal sync information. When not used, these inputs should be left unconnected. For more details about this function and how it should be configured, see the Sync-on-Green Input section.
CLAMP	External Clamp Input.
	This logic input can be used to define the time during which the input signal is clamped to the reference dc level (to ground for RGB or to midscale for YUV). It should be used when the reference dc level is known to be present on the analog input channels, typically during a period following HSYNC, called the back porch, when a good black reference is provided. The CLAMP pin is enabled by setting the external clamp control (Register 0x0F, Bit 7) to 1 (default is 0). When disabled, this pin is ignored and the clamp timing is determined internally by counting a delay and duration from the trailing edge of the HSYNC input. The logic sense of this pin is controlled by the clamp polarity control (Register 0x0F, Bit 6). When not used, this pin should be grounded and the external clamp should be programmed to 0.
COAST	Clock Generator Coast Input (optional).
	This input can be used to stop the pixel clock generator from synchronizing with HSYNC while continuing to produce a clock at its current frequency and phase. This is useful when processing signals from sources that fail to produce horizontal sync pulses during the vertical interval or that include equalization pulses. The COAST signal is usually not required for PC generated signals. The logic sense of this pin is controlled by the coast polarity control (Register 0x0F, Bit 3). When this pin is not used, either ground the pin and program the coast polarity to 1 or tie the pin high (to V <sub>D</sub> through a 10 kΩ resistor) and program the coast polarity to 0. The coast polarity register bit defaults to 1 at power-up.
CKEXT	External Clock Input (optional).
	This pin can be used to provide an external clock to the AD9888 in place of the clock internally generated from HSYNC. The external clock is enabled by programming the external clock select bit (Register 0x15, Bit 0) to 1. When an external clock is used, all other internal functions operate normally. When not used, this pin should be tied through a 10 kΩ resistor to ground, and the external clock register should be programmed to 0. The clock phase adjustment still operates when an external clock source is used.
CKINV	Sampling Clock Inversion (optional).
	This pin can be used to invert the pixel sampling clock, which has the effect of shifting the sampling phase 180°. This supports the alternate pixel sampling mode, wherein higher frequency input signals (up to 410 MSPS) can be captured by first sampling the odd pixels, and then capturing the even pixels on the subsequent frame. This pin should be used only during blanking intervals (typically vertical blanking) because it might produce several samples of corrupted data during the phase shift. When not in use, this pin should be grounded.

Mnemonic	Description
Outputs	
DR <sub>A[7:0]</sub>	Data Output, Red Channel, Port A.
DR <sub>B[7:0]</sub>	Data Output, Red Channel, Port B.
DG <sub>A[7:0]</sub>	Data Output, Green Channel, Port A.
DG <sub>B[7:0]</sub>	Data Output, Green Channel, Port B.
DB <sub>A[7:0]</sub>	Data Output, Blue Channel, Port A.
DB <sub>B[7:0]</sub>	Data Output, Blue Channel, Port B.
	Each channel has two ports. When the part is operated in single-channel mode (channel mode bit (Register 0x15, Bit 7) = 0), all data is presented to Port A, and Port B is placed in a high impedance state. Programming the channel mode bit to 1 establishes dual-channel mode, where pixels are alternately presented to Port A and Port B of each channel. These appear simultaneously; two pixels are presented at the time of every second input pixel when the output mode bit (Register 0x15, Bit 6) is set to 1 (parallel mode). When the output mode bit is set to 0, pixel data appear alternately on the two ports, one new sample with each incoming pixel (interleaved mode). In dual-channel mode, the first pixel after HSYNC is routed to Port A. The second pixel goes to Port B, the third to Port A, and so on. This can be reversed by setting the A/B invert control bit (Register 0x15, Bit 5) to 1. The delay from the pixel sampling time to the output is fixed. When the sampling time is changed by adjusting the clock phase adjust register (Register 0x04, Bits[7:3]), the output timing is shifted as well. The DATA <sub>CK</sub> , $\overline{\text{DATA}}_{\text{CK}}$ , and HSOUT outputs are also moved; therefore, the timing relationship among the signals is maintained.
DATA <sub>CK</sub> , $\overline{\text{DATA}}_{\text{CK}}$	Data Output Clock, Data Output Clock Complement.
	These are differential data clock output signals to be used to strobe the output data and HSOUT into external logic. They are produced by the internal clock generator and are synchronous with the internal pixel sampling clock. When the AD9888 is operated in single-channel mode, the output frequency is equal to the pixel sampling frequency. When operated in dual-channel mode, the clock frequency is half the pixel frequency, as is the output data frequency. When the sampling time is changed by adjusting the clock phase adjust register (Register 0x04, Bits[7:3]), the output timing is shifted as well. The data, DATA <sub>CK</sub> , $\overline{\text{DATA}}_{\text{CK}}$ , and HSOUT outputs are all moved; therefore, the timing relationship among the signals is maintained. Either or both signals can be used, depending on the timing mode and interface design used.
HSOUT	Horizontal Sync Output. This is a reconstructed, phase-aligned version of the HSYNC input. Both the polarity and duration of this output can be programmed via serial bus registers. By maintaining alignment with DATA <sub>CK</sub> , $\overline{\text{DATA}}_{\text{CK}}$ , and data, data timing with respect to horizontal sync can always be determined.
VSOUT	Verical Sync Output.
SOGOUT	Sync-on-Green (SOG) Slicer Output. This pin can be programmed to output either the sync-on-green slicer comparator or an unprocessed but delayed version of the HSYNC input. See the sync processing block diagram (Figure 27) to view how this pin is connected. Note that other than slicing off SOG, the output from this pin receives no other additional processing on the AD9888. VSYNC separation is performed via the sync separator.
REF BYPASS	Internal Reference Bypass. The absolute accuracy of this reference is $\pm 4\%$ , and the temperature coefficient is $\pm 50$ ppm, which is adequate for most AD9888 applications. If higher accuracy is required, an external reference can be employed instead.
RMIDSCV	Red Channel Midscale Voltage Bypass.
BMIDSCV	Blue Channel Midscale Voltage Bypass. These bypasses for the internal midscale voltage references should each be connected to ground through 0.1 $\mu\text{F}$ capacitors. The exact voltage varies with the gain setting of the blue channel.
FILT	External Filter Connection. For proper operation, the internal PLL that generates the pixel clock requires an external filter. Connect the filter shown in Figure 9 to this pin. For optimal performance, minimize noise and parasitics on this node.
Power Supply	
V <sub>D</sub>	Main Power Supply. These pins supply power to the main elements of the circuit. This supply should be as quiet and filtered as possible.
V <sub>DD</sub>	Digital Output Power Supply. A large number of output pins (up to 52) switching at high speed (up to 110 MHz) generates significant power supply transients (noise). These supply pins are identified separately from the V <sub>D</sub> pins; therefore, special care must be taken to minimize output noise transferred into the sensitive analog circuitry. If the AD9888 is interfacing with lower voltage logic, V <sub>DD</sub> can be connected to a lower supply voltage (as low as 2.5 V) for compatibility.
PV <sub>D</sub>	Clock Generator Power Supply. The most sensitive portion of the AD9888 is the clock generation circuitry. These pins provide power to the PLL generated pixel clock and help the user design for optimal performance. The designer should provide noise-free power to these pins.

Mnemonic	Description
GND	Ground. The ground return for all circuitry on the chip. It is recommended that the <a href="#">AD9888</a> be assembled on a single solid ground plane, with careful attention paid to ground current paths.
Serial Port (2-Wire)	For a full description of the 2-wire serial register and how it works, refer to the 2-Wire Serial Control Port section.
SDA	Serial Port Data I/O.
SCL	Serial Port Data Clock.
A0	Serial Port Address Input 1

## DESIGN GUIDE

### GENERAL DESCRIPTION

The [AD9888](#) is a fully integrated solution for capturing analog RGB signals and digitizing them for display on flat panel monitors or projectors. The circuit is ideal for providing a computer interface for HDTV monitors or for serving as the front end of high performance video scan converters.

Implemented in a high performance CMOS process, the interface can capture signals with pixel rates of up to 170 MHz, or of up to 340 MHz with an alternate pixel sampling mode.

The [AD9888](#) includes all necessary input buffering, signal dc restoration (clamping), offset and gain (brightness and contrast) adjustment, pixel clock generation, sampling phase control, and output data formatting. All controls are programmable via a 2-wire serial interface. Full integration of these sensitive analog functions makes system design straightforward and less sensitive to the physical and electrical environment.

With a typical power dissipation of only 920 mW and an operating temperature range of 0°C to 70°C, the device requires no special environmental considerations.

### INPUT SIGNAL HANDLING

The [AD9888](#) has six high impedance analog input pins for the red, green, and blue channels. They accommodate signals ranging from 0.5 V p-p to 1.0 V p-p.

Signals are typically brought onto the interface board via a digital visual interface integrated (DVI-I) connector, a 15-pin D connector, or BNC connectors. The [AD9888](#) should be located as close as possible (or as close as is practical) to the input connector. Signals should be routed via matched impedance traces (normally 75 Ω) to the IC input pins.

At this point, the signal should be resistively terminated (to the signal ground return) and capacitively coupled to the [AD9888](#) inputs through 47 nF capacitors. These capacitors form part of the dc restoration circuit.

If it were possible to have perfectly matched impedances, the best performance would be obtained with the widest possible signal bandwidth. The ultrawide bandwidth inputs of the [AD9888](#) (500 MHz) would track the input signal continuously as it moved from one pixel level to the next, and then digitize the pixel during a long, flat pixel time. In real-world conditions, however, there are mismatches, reflections, and noise, which can result in excessive ringing and distortion of the input waveform. This makes it more difficult to establish a sampling phase that provides good image quality. The [AD9888](#) can digitize graphics signals over a very wide range of frequencies (10 MHz to 170 MHz). Often, characteristics that are beneficial at one frequency can be detrimental at another. Analog bandwidth is one such characteristic. For UXGA resolutions (up to 170 MHz), a very high analog bandwidth is desirable because of the fast input signal slew rates. For VGA and lower

resolutions (down to 12.5 MHz), a very high bandwidth is not desirable because it allows excess noise to pass through. To accommodate these varying needs, the [AD9888](#) includes a variable analog bandwidth control. Four settings are available (75 MHz, 150 MHz, 300 MHz, and 500 MHz), allowing the analog bandwidth to be matched with the resolution of the incoming graphics signal.

Figure 4. Analog Input Interface Circuit

### SYNC PROCESSING OVERVIEW

The [AD9888](#) circuitry enables it to accept composite sync inputs, such as sync-on-green or the trilevel sync inputs found in digital TV signals. A complete description of the sync processing functionality is found in the Sync Slicer and the Sync Separator sections.

### HSYNC AND VSYNC INPUTS

The interface can also accept a horizontal sync signal, which is used to generate the pixel clock and clamp timing. It is possible to operate the [AD9888](#) without applying HSYNC (that is, by using an external clock, external clamp, and single port output mode), but a number of features of the chip will be unavailable; therefore, it is recommended that HSYNC be provided. This can be either a sync signal directly from the graphics source or a preprocessed TTL- or CMOS-level signal.

The HSYNC input includes a Schmitt-trigger buffer for immunity to noise and signals with long rise times. In typical PC-based graphics systems, the sync signals are simply TTL-level drivers feeding unshielded wires in the monitor cable. Therefore, no termination is required or desired.

### SERIAL CONTROL PORT

The serial control port is designed for 3.3 V logic. If there are 5 V drivers on the bus, these pins should be protected with 150 Ω series resistors placed between the pull-up resistors and the input pins.

### OUTPUT SIGNAL HANDLING

The digital outputs are designed and specified to operate from a 3.3 V power supply ( $V_{DD}$ ). They can also work with a  $V_{DD}$  as low as 2.5 V for compatibility with other 2.5 V logic.

### CLAMPING

#### RGB Clamping

To digitize the incoming signal properly, the dc offset of the input must be adjusted to fit the range of the on-board ADCs.

Most graphics systems produce RGB signals with black at ground and white at approximately 0.75 V. However, if sync signals are embedded in the graphics, the sync tip is often at

ground, black is at 300 mV, and white is at approximately 1.0 V. Some common RGB line amplifier boxes use emitter-follower buffers to split signals and increase drive capability. This introduces a 700 mV dc offset to the signal, which must be removed for proper capture by the [AD9888](#).

The key to clamping is to identify a time when the graphics system is known to be producing black. An offset is then introduced, which results in the ADCs producing a black output (Code 0x00) when the known black input is present. The offset then remains in place when other signal levels are processed, and the entire signal is shifted to eliminate offset errors.

In most graphics systems, black is transmitted between active video lines. In CRT displays, when the electron beam has completed writing a horizontal line on the right side of the screen, the beam is deflected quickly to the left side of the screen (called horizontal retrace), and a black signal is provided to prevent the beam from disturbing the image.

In systems with embedded sync, a blacker-than-black signal (HSYNC) is produced briefly to signal the CRT to begin a retrace. It is important to avoid clamping on the tip of HSYNC. Fortunately, there is almost always a period following HSYNC, called the back porch, when a good black reference is provided. This is the time when clamping should be performed.

The clamp timing can be established by simply exercising the CLAMP pin at the appropriate time with external clamp selected (clamp input signal source bit = 1). The polarity of this signal is set by the clamp polarity bit (Register 0x0F, Bit 6).

A simpler method of clamp timing employs the [AD9888](#) internal clamp timing generator. The clamp placement register (Register 0x05) is programmed with the number of pixel times that should pass after the trailing edge of HSYNC before clamping begins. A second register (clamp duration, Register 0x06) sets the duration of the clamp. Both registers are 8-bit values, providing considerable flexibility in clamp generation. The clamp timing is referenced to the trailing edge of HSYNC, because, though HSYNC duration can vary widely, the back porch (black reference) always follows HSYNC. A good starting point for establishing clamping is to set the clamp placement to Value 0x08 (providing eight pixel periods for the graphics signal to stabilize after sync) and set the clamp duration to Value 0x14 (giving the clamp 20 pixel periods to reestablish the black reference).

Clamping is accomplished by placing an appropriate charge on the external input coupling capacitor. The value of this capacitor affects the performance of the clamp. If it is too small, there is a significant amplitude change during a horizontal line time (between clamping intervals). If the capacitor is too large, it takes an excessively long time for the clamp to recover from a large change in incoming signal offset. The recommended value (47 nF) results in recovering from a step error of 100 mV to within 1/2 LSB in 10 lines with a clamp duration of 20 pixel periods on a 60 Hz SXGA signal.

### YUV Clamping

YUV graphics signals are slightly different from RGB signals in that the dc reference level (black level in RGB signals) can be at the midpoint of the video signal rather than at the bottom. For these signals, it might be necessary to clamp to the midscale of the ADC range (Value 0x80) rather than to the bottom of the ADC range (Value 0x00).

Clamping to midscale rather than to ground can be accomplished by setting the clamp select bits in Register 0x10. The red and blue channels each have their own selection bit so that they can be clamped to either midscale or ground independently. The clamp controls are located in Register 0x10, Bit 1 and Bit 2. The midscale reference voltage that each ADC clamps to is provided independently on the RMIDSCV and BMIDSCV pins. These two pins should be bypassed to ground using a 0.1  $\mu$ F capacitor, even if midscale clamping is not required.

### GAIN AND OFFSET CONTROL

The [AD9888](#) can accommodate input signals with inputs ranging from 0.5 V to 1.0 V full scale. The full-scale range is set in three 8-bit registers (red gain, green gain, and blue gain; Register 0x08, Register 0x09, and Register 0x0A, respectively). Increasing the gain setting results in an image with less contrast.

The offset control shifts the entire input range, resulting in a change in image brightness. Three 7-bit registers (red offset, green offset, blue offset; Register 0x0B, Register 0x0C, and Register 0x0D, respectively) provide independent settings for each channel.

The offset controls provide a  $\pm 63$  LSB adjustment range. This range is connected with the full-scale range. Therefore, if the input range is doubled (from 0.5 V to 1.0 V), the offset step size is also doubled (from 2 mV per step to 4 mV per step).

Figure 5 illustrates the interaction of gain and offset controls. The magnitude of an LSB in offset adjustment is proportional to the full-scale range; therefore, changing the full-scale range also changes the offset. The change is minimal if the offset setting is near midscale. When changing the offset, the full-scale range is not affected, but the full-scale level is shifted by the same amount as the zero-scale level.

Figure 5. Gain and Offset Control

**SYNC-ON-GREEN INPUT**

The sync-on-green input operates in two steps. First, with the aid of a negative peak detector, it sets a baseline clamp level from the incoming video signal. Second, it sets the threshold level (nominally 150 mV above the negative peak). The exact threshold level is variable and can be programmed via Register 0x10. The sync-on-green input must be ac-coupled to the green analog input through its own capacitor, as shown in Figure 6. The value of the capacitor must be 1 nF ± 20%. If sync-on-green input is not used, this connection is not required and the SOGIN pin should be left unconnected. (Note that the sync-on-green signal is always negative polarity.) For more details, see the Sync Processing Overview section.

Figure 6. Typical Clamp Configuration for RGB/YUV Applications

**CLOCK GENERATION**

A PLL is employed to generate the pixel clock. The HSYNC input provides a reference frequency to the PLL. A voltage controlled oscillator (VCO) generates a much higher pixel clock frequency. This pixel clock is divided by the PLL divide value (Register 0x01 and Register 0x02), and the phase is compared with the HSYNC input. Any error is used to shift the VCO frequency and maintain lock between the two signals.

The stability of this clock is very important for providing the clearest and most stable image. During each pixel time, there is a period during which the signal is slewing from the old pixel amplitude and settling to a new value. Then, the input voltage is stable until the signal slews to a new value (see Figure 7). The ratio of the slewing time to the stable time is a function of the bandwidth of the graphics DAC, the bandwidth of the transmission system (cable and termination), and the overall pixel rate. Therefore, if the dynamic characteristics of the system

remain fixed, the slewing and settling times are likewise fixed. These times must be subtracted from the total pixel period to determine the stable period. At higher pixel frequencies, both the total cycle time and stable pixel time are shorter.

Figure 7. Pixel Sampling Times

Any jitter in the clock reduces the precision with which the sampling time can be determined, and must be subtracted from the stable pixel time. The AD9888 clock generation circuit is designed to minimize jitter to less than 9% of the total pixel time in all operating modes, making its effect on valid sampling time negligible (see Figure 8).

Figure 8. Pixel Clock Jitter vs. Frequency

The PLL characteristics are determined by the loop filter design, the PLL charge pump current, and the VCO range setting. The loop filter design is illustrated in Figure 9.

Recommended settings of VCO range and charge pump current for VESA standard display modes are listed in Table 5.

Figure 9. PLL Loop Filter Detail

<sup>1</sup> Graphics sampled at half the incoming pixel rate using alternate pixel sampling mode.

Four programmable registers are provided to optimize the performance of the PLL:

- The 12-bit divisor registers. The input HSYNC frequencies range from 15 kHz to 110 kHz. The PLL multiplies the frequency of the HSYNC signal, producing pixel clock frequencies in the range of 10 MHz to 170 MHz. The divisor register controls the exact multiplication factor. This register can be set to any value between 221 and 4095. (The divide ratio that is actually used is the programmed divide ratio plus one.)
- The 2-bit VCO range register. To lower the sensitivity of the output frequency to noise on the control signal, the VCO operating frequency range is divided into four overlapping regions. The VCO range register sets this operating range. Because there are just four possible regions, only the two least significant bits of the VCO range register are used. The frequency ranges for the lowest and highest regions are shown in Table 6.

Table 6. VCO Frequency Ranges

PV1	PV0	Pixel Clock Range (MHz)	KVCO Gain (MHz/V)
0	0	10 to 41	150
0	1	41 to 82	150
1	0	82 to 150	150
1	1	150+	180

- The 3-bit charge pump current register. This register allows the current that drives the low-pass loop filter to be varied. The possible current values are listed in Table 7.

Table 7. Charge Pump Current/Control Bits

Ip2	Ip1	Ip0	Current (μA)
0	0	0	50
0	0	1	100
0	1	0	150
0	1	1	250
1	0	0	350
1	0	1	500
1	1	0	750
1	1	1	1500

- The 5-bit phase adjust register. The phase of the generated sampling clock may be shifted to locate an optimum sampling point within a clock cycle. The phase adjust register provides 32 phase-shift steps of 11.25° each. The HSYNC signal with an identical phase shift is available through the HSOUT pin. Phase adjustment is still available if the pixel clock is being provided externally. The COAST pin is used to allow the PLL to continue to run at the same frequency in the absence of the incoming HSYNC signal. This can be used during the vertical sync period, or any other time that the HSYNC signal is unavailable. The polarity of the COAST signal can be set through the coast polarity register, and the polarity of the HSYNC signal can be set through the HSYNC polarity register.

**ALTERNATE PIXEL SAMPLING MODE**

A Logic 1 input on the clock invert pin (CKINV, Pin 29) inverts the nominal ADC clock. CKINV can be switched between frames to implement the alternate pixel sampling mode. This allows higher effective image resolution to be achieved at lower pixel rates, but with lower frame rates.

On one frame, only even pixels are digitized. On the subsequent frame, odd pixels are sampled. By reconstructing the entire frame in the graphics controller, a complete image can be reconstructed. This is similar to the interlacing process employed in broadcast television systems, but the interlacing is vertical instead of horizontal. The frame data is still presented to the display at the full desired refresh rate (usually 60 Hz), so there are no flicker artifacts added.

Figure 12. Odd Pixels from Frame 1

Figure 13. Combined Frame Output from Graphics

Figure 14. Subsequent Frame from Controller

**TIMING**

Figure 16 through Figure 25 show the operation of the AD9888 analog interface in all clock modes. The part establishes timing by sending the pixel corresponding with the leading edge of HSYNC to the A data port. In dual-channel mode, the next sample is to the B data port. Subsequent samples are alternated between the A and B data ports. In single-channel mode, data is sent to the A data port only, and the B data port is placed in a high impedance state. The output data clock signal is created so that its rising edge always occurs between transitions of the A port data and so that it can be used to latch the output data externally.

Figure 15. Output Timing

**HSYNC Timing**

Horizontal sync is processed in the AD9888 to eliminate ambiguity in the timing of the leading edge with respect to the phase-delayed pixel clock and data.

The HSYNC input is used as a reference to generate the pixel sampling clock. To optimize the pixel sampling time, the sampling phase can be adjusted with respect to HSYNC through a full 360° in 32 steps via the clock phase adjust register. Display systems

use HSYNC to align memory and display write cycles; therefore, it is important to have a stable timing relationship between the HSYNC output (HSOUT) and data clock (DATAACK).

Three things happen to horizontal sync in the AD9888. First, the polarity of HSYNC input is determined and, therefore, has a known output polarity. The known output polarity can be programmed either active high or active low (Register 0x0E, Bit 5). Second, HSOUT is aligned with DATAACK and data outputs. Third, the duration of HSOUT (in pixel clocks) is set via Register 0x07. HSOUT is the sync signal that should be used to drive the rest of the display system.

**Coast Timing**

In most computer systems, the HSYNC signal is provided continuously on a dedicated wire. In these systems, the COAST input and function are unnecessary and should not be used. In some systems, however, HSYNC is disturbed during the vertical sync period (VSYNC). In some cases, HSYNC pulses disappear. In other systems, such as those that use composite sync (Csync) or embedded sync-on-green (SOG) signals, HSYNC includes equalization pulses or other distortions during VSYNC. To avoid upsetting the clock generator during VSYNC, it is important to ignore these distortions. If the PLL generated pixel clock sees extraneous pulses, it attempts to lock to this new frequency and changes frequency by the end of the VSYNC period. It then requires a few lines of correct HSYNC timing to recover at the beginning of a new frame, resulting in a “tearing” of the image at the top of the display.

The COAST input pin is provided to eliminate this problem. It is an asynchronous input that disables the PLL input and holds the clock at its current frequency. The PLL can operate in this manner for several lines without significant frequency drift.

## 2-WIRE SERIAL REGISTER MAP

The AD9888 is initialized and controlled by a set of registers that determine the operating modes. An external controller is employed to write and read the control registers through the two-line serial interface port.

Table 8. Control Register Map

Hex Address	Read and Write, or Read Only	Bits	Default Value	Register Name	Function
0x00	RO	[7:0]		Chip revision	An 8-bit register that represents the silicon revision level.
0x01	R/W	[7:0]	01101001	PLL divider MSB	MSBs (Bits[11:4]) of the PLL divider word. Larger values mean the PLL operates at a faster rate. This register should be loaded first whenever a change is needed to allow the PLL more time to lock. <sup>1</sup>
0x02	R/W	[7:4]	1101****	PLL divider LSB	LSBs of the PLL divider word. <sup>1</sup>
0x03	R/W	[7:3]	01*****	VCO range select/charge pump current	Bits[7:6]—VCO range. Selects VCO frequency range. See the Clock Generation section.  Bits[5:3]—charge pump current. Varies the current that drives the low-pass filter. See the Clock Generation section.
0x04	R/W	[7:3]	10000***	Clock Phase adjust	ADC Clock phase adjustment. Larger values mean more delay. (1 LSB = $t/32$ )
0x05	R/W	[7:0]	00001000	Clamp placement	Places the CLAMP signal an integer number of clock periods after the trailing edge of the HSYNC signal.
0x06	R/W	[7:0]	00010100	Clamp duration	Number of clock periods that the CLAMP signal is actively clamping.
0x07	R/W	[7:0]	00100000	HSYNC output pulse width	Sets the number of pixel clocks that HSOUT remains active.
0x08	R/W	[7:0]	10000000	Red gain	Controls the ADC input range (contrast) of the red channel. Bigger values result in less contrast.
0x09	R/W	[7:0]	10000000	Green gain	Same function as the red gain bits, but for the green channel.
0x0A	R/W	[7:0]	10000000	Blue gain	Same function as the red gain bits, but for the blue channel.
0x0B	R/W	[7:1]	1000000*	Red offset	Controls dc offset (brightness) of the red channel. Bigger values decrease brightness.
0x0C	R/W	[7:1]	1000000*	Green offset	Same function as the red offset bits, but for the green channel.
0x0D	R/W	[7:1]	1000000*	Blue offset	Same function as the red offset bits, but for the blue channel.
0x0E	R/W	[7:0]	0*****	Sync control	Bit 7—HSYNC input polarity override. Logic 0 = polarity determined by chip; Logic 1 = polarity set by Bit 6 in Register 0x0E. Bit 6—HSYNC input polarity. Indicates to the PLL the polarity of the incoming HSYNC signal. Logic 0 = active low; Logic 1 = active high. Bit 5—HSYNC output polarity. Logic 0 = logic high sync; Logic 1 = logic low sync. Bit 4—active HSYNC override. Logic 1 = the user can select the HSYNC to be used via Bit 3; Logic 0 = the active interface is selected via Bit 6 in Register 0x14. Bit 3—active HSYNC select. Logic 0 = selects HSYNC as the active sync; Logic 1 = selects sync-on-green as the active sync. Note that the indicated HSYNC is used only if Bit 4 is set to Logic 1 or if both syncs are active (Bit 1 and Bit 7 are set to Logic 1 in Register 0x14). Bit 2—VSYNC output invert. Logic 0 = invert; Logic 1 = no invert. Bit 1—active VSYNC override. Logic 1 = the user can select the VSYNC to be used via Bit 0; Logic 0 = the active interface is selected via Bit 3 in Register 0x14. Bit 0—active VSYNC select. Logic 0 = selects raw VSYNC as the output VSYNC; Logic 1 = selects sync separated VSYNC as the output VSYNC. Note that the indicated VSYNC is used only if Bit 1 is set to Logic 1.

<sup>1</sup> The AD9888 updates the PLL divide ratio only when the LSBs of the PLL divider are written to in Register 0x02.

## 2-WIRE SERIAL CONTROL REGISTER DETAILS

### CHIP IDENTIFICATION

#### Address 0x00[7:0]—Chip Revision

An 8-bit register that represents the silicon revision.

### PLL DIVIDER CONTROL

#### Address 0x01[7:0]—PLL Divide Ratio MSBs

The eight MSBs of the 12-bit PLL divide ratio (PLLDIV). The operational divide ratio is PLLDIV + 1.

The PLL derives a master clock from an incoming HSYNC signal. The master clock frequency is then divided by an integer value, such that the output is phase locked to HSYNC. This PLLDIV value determines the number of pixel times (pixels plus horizontal blanking overhead) per line. This is typically 20% to 30% more than the number of active pixels in the display.

The 12-bit value of the PLL divider supports divide ratios from 2 to 4095. The higher the value loaded in this register, the higher the resulting clock frequency with respect to a fixed HSYNC frequency.

VESA has established standard timing specifications that assist in determining the value for PLLDIV as a function of horizontal and vertical display resolution and frame rate (see Table 5). However, many computer systems do not conform precisely to the recommendations, and these numbers should be used only as a guide. The display system manufacturer should provide automatic or manual means for optimizing PLLDIV. An incorrectly set PLLDIV usually produces one or more vertical noise bars on the display. The greater the error, the greater the number of bars produced.

The power-up default value of PLLDIV is 1693 (PLLDIVM = 0x69, PLLDIVL = 0xDx).

The AD9888 updates the full divide ratio only when the LSBs are changed. Writing to this register by itself does not trigger an update.

#### Address 0x02[7:4]—PLL Divide Ratio LSBs

The four LSBs of the 12-bit PLL divide ratio (PLLDIV). The operational divide ratio is PLLDIV + 1.

The power-up default value of PLLDIV is 1693 (PLLDIVM = 0x69, PLLDIVL = 0xDx).

The AD9888 updates the full divide ratio only when this register is written to.

### CLOCK GENERATOR CONTROL

#### Address 0x03[7:6]—VCO Range Select

Two bits that establish the operating range of the clock generator.

The VCO range must be set to correspond with the desired operating frequency (incoming pixel rate).

The PLL provides the best jitter performance at high frequencies. To output low pixel rates while minimizing jitter, the PLL operates at a higher frequency and then divides down the clock rate afterwards. Table 9 shows the pixel rates for each VCO range setting.

The PLL output divisor is automatically selected with the VCO range setting.

**Table 9. VCO Ranges Settings**

VCO Range Select Setting	Data Clock Range (MHz)
00	10 to 41
01 (default)	41 to 82
10	82 to 150
11	150+

#### Address 0x03[5:3]—Charge Pump Current

Three bits that establish the current driving the loop filter in the clock generator. These bits must be set to correspond with the desired operating frequency (incoming pixel rate).

**Table 10. Charge Pump Current Settings**

Charge Pump Current Setting	Current (mA)
000	50
001 (default)	100
010	150
011	250
100	350
101	500
110	750
111	1500

#### Address 0x04[7:3]—Clock Phase Adjust

A 5-bit value that adjusts the sampling phase in 32 steps across one pixel time. Each step represents an 11.25° shift in sampling phase.

The power-up default value is 16.

### CLAMP TIMING

#### Address 0x05[7:0]—Clamp Placement

An 8-bit register that sets the position of the internally generated clamp.

When the external clamp control bit is set to 0, a CLAMP signal is generated internally after the trailing edge of HSYNC at a position (in pixel periods) established by the clamp placement bits and for a duration (in pixel periods) set by the clamp duration bits. The clamp placement can be programmed to any value up to 255, except 0.

The clamp should be placed during a time when the input signal presents a stable black level reference, usually the back porch period between HSYNC and the image.

When the external clamp control bit is set to 1, this register is ignored.

#### Address 0x06[7:0]—Clamp Duration

An 8-bit register that sets the duration of the internally generated clamp.

When the external clamp control bit is set to 0, a CLAMP signal is generated internally after the trailing edge of HSYNC at a position

(in pixel periods) established by the clamp placement bits and for a duration (in pixel periods) set by the clamp duration bits. The clamp duration can be programmed to any value between 1 and 255. A value of 0 is not supported.

For the best results, the clamp duration should be set to include the majority of the black reference signal time that follows the HSYNC signal trailing edge. Insufficient clamping time can produce brightness changes at the top of the screen and a slow recovery from large changes in the average picture level (APL), or brightness.

When the external clamp control bit is set to 1, this register is ignored.

### HSYNC PULSE WIDTH

#### **Address 0x07[7:0]—HSYNC Output Pulse Width**

An 8-bit register that sets the duration of the HSYNC output pulse.

The leading edge of the HSYNC output is triggered by the internally generated, phase-adjusted PLL feedback clock. The AD9888 then counts a number of pixel clocks equal to the value in this register. This triggers the trailing edge of the HSYNC output, which is also phase adjusted.

### INPUT GAIN

#### **Address 0x08[7:0]—Red Channel Gain Adjust (Red Gain)**

An 8-bit word that sets the gain of the red channel.

The AD9888 can accommodate input signals with a full-scale range between 0.5 V p-p and 1.0 V p-p. Setting red gain to 255 corresponds to an input range of 1.0 V p-p. A red gain of 0 establishes an input range of 0.5 V p-p. Note that increasing red gain results in the picture having less contrast because the input signal uses fewer of the available converter codes (see Figure 5). The same functionality also applies to the green and blue channel gain adjust bits.

#### **Address 0x09[7:0]—Green Channel Gain Adjust (Green Gain)**

An 8-bit word that sets the gain of the green channel (see the Address 0x08[7:0]—Red Channel Gain Adjust (Red Gain) section for more information).

#### **Address 0x0A[7:0]—Blue Channel Gain Adjust (Blue Gain)**

An 8-bit word that sets the gain of the blue channel (see the Address 0x08[7:0]—Red Channel Gain Adjust (Red Gain) section for more information).

### INPUT OFFSET

#### **Address 0x0B[7:1]—Red Channel Offset Adjust (Red Offset)**

A 7-bit offset binary word that sets the dc offset of the red channel.

One LSB of offset adjustment equals approximately one LSB change in the ADC offset. Therefore, the absolute magnitude of the offset

adjustment scales as the gain of the channel changes. A nominal setting of 63 results in the channel nominally clamping to Code 00 during the back porch clamping interval. An offset setting of 127 results in the channel clamping to Code 64 of the ADC. An offset setting of 0 clamps to Code –63. Increasing the value of red offset decreases the brightness of the channel. The same functionality also applies to the green and blue channel offset adjust bits.

#### **Address 0x0C[7:1]—Green Channel Offset Adjust (Green Offset)**

A 7-bit offset binary word that sets the dc offset of the green channel (see the Address 0x0B[7:1]—Red Channel Offset Adjust (Red Offset) section for more information).

#### **Address 0x0D[7:1]—Blue Channel Offset Adjust (Blue Offset)**

A 7-bit offset binary word that sets the dc offset of the blue channel (see the Address 0x0B[7:1]—Red Channel Offset Adjust (Red Offset) section for more information).

### SYNC CONTROL

#### **Address 0x0E[7]—HSYNC Input Polarity Override**

This register is used to override the internal circuitry that determines the polarity of the HSYNC signal going into the PLL.

**Table 11. HSYNC Input Polarity Override Settings**

HSYNC Input Polarity Override Setting	Function
0 (default)	HSYNC polarity is determined by chip.
1	HSYNC polarity is determined by user.

#### **Address 0x0E[6]—HSYNC Input Polarity**

This bit must be set to indicate the polarity of the HSYNC signal that is applied to the PLL HSYNC input.

**Table 12. HSYNC Input Polarity Settings**

HSYNC Input Polarity Setting	Function
0	Active low
1 (default)	Active high

Active low means that the leading edge of the HSYNC pulse is negative-going and, therefore, timing is based on the leading edge of HSYNC, which is the falling edge. The rising edge has no effect.

Active high means that the leading edge of the HSYNC pulse is positive-going and, therefore, timing is based on the leading edge of HSYNC, which is the rising edge.

Although the device can operate if this bit is set incorrectly, the internally generated clamp position, as established by the clamp placement (Register 0x05), will not be placed as expected, which may generate clamping errors.

**Address 0x0E[5]—HSYNC Output Polarity**

This bit determines the polarity of the HSYNC output and the SOG output (see Table 13).

**Table 13. HSYNC Output Polarity Settings**

HSYNC Output Polarity Setting	Function
0 (default)	Logic 1 (positive polarity)
1	Logic 0 (negative polarity)

**Address 0x0E[4]—Active HSYNC Override**

This bit is used to override the automatic HSYNC selection. To initiate this override, set this bit to Logic 1. When overriding the automatic HSYNC selection, the active HSYNC is set via Bit 3 in this register.

**Table 14. Active HSYNC Override Settings**

Active HSYNC Override Setting	Function
0 (default)	Bit 6 in Register 0x14 determines the active interface.
1	Override, Bit 3 determines the active interface.

**Address 0x0E[3]—Active HSYNC Select**

This bit is used under two conditions. It is used to select the active HSYNC when the override bit (Register 0x0E, Bit 4) is set. Alternatively, it is used to determine the active HSYNC when the override bit is not set but both HSYNCs are detected.

**Table 15. Active HSYNC Select Settings**

Active HSYNC Select Setting	Function
0 (default)	HSYNC input
1	Sync-on-green input

**Address 0x0E[2]—VSYNC Output Invert**

This bit inverts the polarity of the VSYNC output (see Table 16).

**Table 16. VSYNC Output Polarity Settings**

VSYNC Output Invert Setting	Function
0 (default)	Invert
1	Do not invert

**Address 0x0E[1]—Active VSYNC Override**

This bit is used to override the automatic VSYNC selection. To initiate this override, set this bit to Logic 1. When overriding the automatic VSYNC selection, the active interface is set via Bit 0 in this register.

**Table 17. Active VSYNC Override Settings**

Active VSYNC Override Setting	Function
0 (default)	Bit 3 in Register 0x14 determines the active VSYNC.
1	Override, Bit 0 determines the active VSYNC.

**Address 0x0E[0]—Active VSYNC Select**

This bit is used to select the active VSYNC when the override bit (Register 0x0E, Bit 1) is set.

**Table 18. Active VSYNC Select Settings**

Active VSYNC Select Setting	Function
0 (default)	VSYNC input
1	Sync separator output

**INPUT CONTROL****Address 0x0F[7]—Clamp Input Signal Source**

This bit determines the source of clamp timing.

**Table 19. Clamp Input Signal Source Settings**

Clamp Input Signal Source Setting	Function
0 (default)	Internally generated clamp
1	Externally provided clamp signal

A 0 enables the clamp timing circuitry controlled by clamp placement and clamp duration. The clamp position and duration is counted from the trailing edge of HSYNC.

A 1 enables the external CLAMP input pin. The three channels are clamped when the CLAMP signal is active. The polarity of CLAMP is determined by the clamp input signal polarity bit (Register 0x0F, Bit 6).

**Address 0x0F[6]—Clamp Input Signal Polarity**

This bit determines the polarity of the externally provided CLAMP signal.

**Table 20. Clamp Input Signal Polarity Settings**

CLAMP Input Signal Polarity Setting	Function
0	Active high
1 (default)	Active low

A Logic 1 means the circuit clamps when CLAMP is low and passes the signal to the ADC when CLAMP is high.

A Logic 0 means the circuit clamps when CLAMP is high and passes the signal to the ADC when CLAMP is low.

**Address 0x0F[5]—Coast Select**

This bit is used to select the active coast source. The choices are the COAST input pin or VSYNC. If VSYNC is selected, users must decide whether to use the VSYNC input pin or the output from the sync separator (Register 0x0E, Bit 1 and Bit 0).

**Table 21. Coast Source Selection Settings**

Coast Select Setting	Function
0 (default)	COAST input pin
1	VSYNC (must choose VSYNC input pin or output from sync separator)

**Address 0x0F[4]—Coast Input Polarity Override**

This bit is used to override the internal circuitry that determines the polarity of the COAST signal going into the PLL.

**Table 22. Coast Input Polarity Override Settings**

Coast Input Polarity Override Setting	Function
0 (default)	Coast polarity is determined by chip.
1	Coast polarity is determined by user.

**Address 0x0F[3]—Coast Input Polarity**

This bit indicates the polarity of the COAST signal that is applied to the PLL coast input.

**Table 23. Coast Input Polarity Settings**

Coast Input Polarity Setting	Function
0	Active low
1 (default)	Active high

Active low means that the clock generator ignores HSYNC inputs when COAST is low and continues operating at the same nominal frequency until COAST goes high.

Active high means that the clock generator ignores HSYNC inputs when COAST is high and continues operating at the same nominal frequency until COAST goes low.

This function needs to be used along with the coast polarity override bit (Bit 4).

**Address 0x0F[2]—Seek Mode Override**

This bit is used to either enable or disable the low power mode. The low power mode (seek mode) occurs when there are no signals on any of the sync inputs.

**Table 24. Seek Mode Override Settings**

Seek Mode Override Setting	Function
0	Disable seek mode
1 (default)	Enable seek mode

**Address 0x0F[1]—PWRDN**

This bit is used to put the chip into power-down mode. In this mode, the power dissipation of the chip is reduced to a fraction of the typical power (see the specifications in Table 1 for exact power dissipation). When the chip is in power-down mode, the HSOUT, VSOUT, DATAACK, and all 48 of the data outputs are put into a high impedance state. Note that the SOGOUT output is not put into high impedance. Circuit blocks that continue to be active during power-down mode include the voltage references, sync processing, sync detection, and the serial register. These blocks facilitate a fast startup from power-down.

**Table 25. PWRDN Settings**

PWRDN Setting	Function
0	Power-down
1 (default)	Normal operation

**Address 0x10[7:3]—Sync-on-Green Slicer Threshold**

These bits allow the comparator threshold of the sync-on-green slicer to be adjusted. The threshold can be adjusted in steps of 10 mV, with a minimum setting of 10 mV and a maximum setting of 330 mV.

The default setting is 01111, which corresponds to a threshold value of 0.16 V.

**Address 0x10[2]—Red Clamp Select**

This bit determines whether the red channel is clamped to ground or to midscale. For RGB video, all three channels are referenced to ground. For YCbCr (or YUV), the Y channel is referenced to ground, but the CbCr channels are referenced to midscale. Clamping to midscale clamps to Pin 9.

**Table 26. Red Clamp Select Settings**

Red Clamp Select Setting	Function
0 (default)	Clamp to ground
1	Clamp to midscale (Pin 9)

**Address 0x10[1]—Blue Clamp Select**

This bit determines whether the blue channel is clamped to ground or to midscale. Clamping to midscale clamps to Pin 24.

**Table 27. Blue Clamp Select Settings**

Blue Clamp Select Setting	Function
0 (default)	Clamp to ground
1	Clamp to midscale (Pin 24)

**Address 0x11[7:0]—Sync Separator Threshold**

These bits are used to set the responsiveness of the sync separator. The bits set how many internal 5 MHz clock periods the sync separator must count before toggling high or low. This functions like a low-pass filter to ignore HSYNC pulses to extract the VSYNC signal. The bits should be set to a number greater than the maximum HSYNC pulse width. The sync separator threshold uses an internal dedicated clock with a frequency of approximately 5 MHz.

The default for this register is 0x20.

**Address 0x12[7:0]—Pre-COAST**

These bits allow the COAST signal to be applied prior to the VSYNC signal. This is necessary in cases where preequalization pulses are present. The step size for this control is one HSYNC period.

The default is 0.

**Address 0x13[7:0]—Post-COAST**

This register allows the COAST signal to be applied after the VSYNC signal. This is necessary in cases where postequalization pulses are present. The step size for this control is one HSYNC period.

The default setting for each of these bits is 0.

**Address 0x14[7]—HSYNC Detect**

This bit indicates when activity is detected on the selected HSYNC input pin. If HSYNC is held high or low, activity is not detected.

**Table 28. HSYNC Detection Results**

HSYNC Detect Setting	Function
0	No activity detected
1	Activity detected

The sync processing block diagram (Figure 27) shows where this function is implemented.

**Address 0x14[6]—Active HSYNC (AHS)**

This bit indicates which horizontal sync input source (HSYNC or SOG) is used by the PLL (see Table 29). When AHS is 0, the HSYNC pin is used. When AHS is 1, the SOG pin is used.

Determine which source is active by using Bit 7 and Bit 1 in this register. Bit 7 indicates when activity is detected on HSYNC, and Bit 1 indicates when activity is detected on SOG. If activity is detected on both HSYNC and SOG, the user can determine which has priority via Bit 3 in Register 0x0E. The user can override the function of AHS via Bit 4 in Register 0x0E. If the override bit is set to Logic 1, AHS is forced to the state that Bit 3 is set to in Register 0x0E.

**Table 29. Active HSYNC Settings**

Active HSYNC Setting	Function
1	SOG pin is used for HSYNC input
0	HSYNC pin is used for HSYNC input

**Table 30. Active HSYNC Results**

Bit 7 in 0x14 (HSYNC Detect)	Bit 1 in 0x14 (SOG Detect)	Bit 4 in 0x0E (Override)	AHS
0	0	0	N/A (use Bit 3 in 0x0E)
0	1	0	1
1	0	0	0
1	1	0	N/A (use Bit 3 in 0x0E)
X <sup>1</sup>	X <sup>1</sup>	1	N/A (use Bit 3 in 0x0E)

<sup>1</sup>X = don't care.

**Address 0x14[5]—Detected HSYNC Input Polarity Status**

This bit reports the status of the HSYNC input polarity detection circuit. It can be used to determine the polarity of the HSYNC input. The location of the detection circuit is shown in the sync processing block diagram (Figure 27).

**Table 31. Detected HSYNC Input Polarity Status**

Detected HSYNC Input Polarity Status Setting	Function
0	HSYNC polarity is negative.
1	HSYNC polarity is positive.

**Address 0x14[4]—VSYNC Detect**

This bit is used to indicate when activity is detected on the selected VSYNC input pin. If VSYNC is held high or low, activity is not detected.

**Table 32. VSYNC Detection Status**

VSYNC Detect Setting	Function
0	No activity detected
1	Activity detected

The sync processing block diagram (Figure 27) shows where this function is implemented.

**Address 0x14[3]—Active VSYNC (AVS)**

This bit indicates which VSYNC source is being used: the VSYNC input or the output from the sync separator. When AVS is 1, the sync separator is used. When AVS is 0, the VSYNC input is used.

Determine which source is active by using Bit 4 and Bit 1 in this register. Bit 4 indicates when activity is detected on VSYNC, and Bit 1 indicates when activity is detected on SOG. If activity is detected on both VSYNC and SOG, the user can determine which has priority via Bit 0 in Register 0x0E. The user can override the function of AVS via Bit 1 in Register 0x0E. If the override bit is set to Logic 1, AVS is forced to the state that Bit 0 is set to in Register 0x0E.

**Table 33. Active VSYNC Settings**

Active VSYNC Setting	Function
1	The sync separator is used
0	The VSYNC input is used

**Table 34. Active VSYNC Results**

Bit 4 in 0x14 (VSYNC Detect)	Bit 1 in 0x14 (SOG Detect)	Bit 1 in 0x0E (Override)	AVS
0	0	0	1
1	1	0	0
X <sup>1</sup>	X <sup>1</sup>	1	N/A (use Bit 0 in 0x0E)

<sup>1</sup>X = don't care.

**Address 0x14[2]—Detected VSYNC Output Polarity Status**

This bit indicates the status of the VSYNC output polarity detection circuit and can be used to determine the polarity of the VSYNC input. The location of the detection circuit is shown in the sync processing block diagram (Figure 27).

**Table 35. Detected VSYNC Input Polarity Status**

Detected VSYNC Output Polarity Status Setting	Function
0	VSYNC polarity is active high.
1	VSYNC polarity is active low.

**Address 0x14[1]—Sync-on-Green Detect**

This bit indicates when sync activity is detected on the selected sync-on-green input pin.

**Table 36. Sync-on-Green Detection Status**

Sync-on-Green Detect Setting	Function
0	No activity detected
1	Activity detected

The sync processing block diagram (Figure 27) shows where this function is implemented.

**Address 0x14[0]—Detected Coast Polarity Status**

This bit reports the status of the coast input polarity detection circuit and can be used to determine the polarity of the coast input. The location of the detection circuit is shown in Figure 27.

**Table 37. Detected Coast Input Polarity Status**

Detected Coast Polarity Status Setting	Function
0	Coast polarity is negative.
1	Coast polarity is positive.

**MODE CONTROL 1****Address 0x15[7]—Channel Mode (DEMUX)**

This bit determines whether all pixels are presented to a single port (Port A) or if pixels are alternately demultiplexed to Port A and Port B.

**Table 38. Output Port Mode Settings**

Channel Mode Setting	Function
0	All data goes to Port A.
1 (default)	Pixels are alternately presented to Port A and Port B.

When DEMUX = 0, Port B outputs are in a high impedance state. The maximum data rate for single-port mode is 110 MHz. The timing diagrams in Figure 16 to Figure 18 show the effects of this option.

**Address 0x15[6]—Output Mode**

This bit determines whether all pixels are presented to Port A and Port B simultaneously upon every second DATAACK rising edge or if pixels are alternately presented to Port A and Port B upon successive DATAACK rising edges.

**Table 39. Output Mode Settings**

Output Mode Setting	Function
0	Data is interleaved.
1 (default)	Data is simultaneous on every other data clock.

When in single-port mode (DEMUX = 0), this bit is ignored. When in dual-port mode, the Figure 19 to Figure 24 timing diagrams show the effects of this option.

**Address 0x15[5]—A/B Invert Control (OUTPHASE)**

This bit determines whether even pixels or odd pixels go to Port A.

**Table 40. A/B Invert Control Settings**

A/B Invert Control Setting	First Pixel after HSYNC
0 (default)	Port A
1	Port B

In normal operation (OUTPHASE = 0) when operating in dual-port output mode (DEMUX = 1), the first sample after the HSYNC leading edge is presented at Port A. Every subsequent odd sample goes to Port A. All even samples go to Port B.

When OUTPHASE = 1, these ports are reversed and the first sample goes to Port B.

When DEMUX = 0, this bit is ignored because data always comes out of only Port A.

**Address 0x15[4]—4:2:2 Output Mode Select**

This bit configures the output data in 4:2:2 mode. This mode can be used to reduce the number of data lines used from 24 to 16 for applications using YUV, YCbCr, or YPbPr graphics signals. A timing diagram for this mode is shown in Figure 25. Recommended input and output configurations are shown in Table 42. In 4:2:2 mode, the red and blue channels can be interchanged to help satisfy board layout or timing requirements, but the green channel must be configured for Y.

**Table 41. 4:2:2 Output Mode Select Settings**

4:2:2 Output Mode Select Setting	Output Mode
0 (default)	4:4:4
1	4:2:2

**Table 42. 4:2:2 Input/Output Configuration**

Channel	Input Connection	Output Format
Red	V	U/V
Green	Y	Y
Blue	U	High impedance

**Address 0x15[3]—Input Mux Control**

This bit selects analog inputs from either Channel 0 or Channel 1.

**Table 43. Input Mux Control Settings**

Input Mux Control Setting	Channel Selected
0 (default)	Channel 0
1	Channel 1

**Address 0x15[2:1]—Analog Bandwidth Control**

These bits select the analog bandwidth.

**Table 44. Analog Bandwidth Control Settings**

Analog Bandwidth Control Setting	Analog Bandwidth
00	75 MHz
01	150 MHz
10	300 MHz
11 (default)	500 MHz

**Address 0x15[0]—External Clock Select**

This bit determines the source of the pixel clock.

**Table 45. External Clock Select Settings**

External Clock Select Setting	Function
0 (default)	Internally generated clock
1	Externally provided clock signal

A Logic 0 enables the internal PLL that generates the pixel clock from an externally provided HSYNC.

A Logic 1 enables the external CKEXT input pin. In this mode, the PLL divide ratio (PLLDIV) is ignored. The clock phase adjust register is still functional.

## 2-WIRE SERIAL CONTROL PORT

A 2-wire serial control interface is provided. Up to two [AD9888](#) devices can be connected to the 2-wire serial interface, with each device having a unique address.

The 2-wire serial interface comprises a clock (SCL) and a bidirectional data (SDA) pin. The [AD9888](#) acts as a slave for receiving and transmitting data over the serial interface. When the serial interface is not active, the logic levels on SCL and SDA are pulled high by external pull-up resistors.

Data received or transmitted on the SDA line must be stable for the duration of the positive-going SCL pulse. Data on SDA must change only when SCL is low. If SDA changes state while SCL is high, the serial interface interprets the action as a start or stop sequence.

There are five components to serial bus operation:

- Start signal
- Slave address byte
- Base register address byte
- Data byte to read or write
- Stop signal

When the serial interface is inactive (SCL and SDA are high), communications are initiated by sending a start signal. The start signal is a high-to-low transition on SDA while SCL is high. This signal alerts all slaved devices that a data transfer sequence is imminent.

The first eight bits of data transferred after a start signal compose a 7-bit slave address (the first seven bits) and a single  $\overline{R/\overline{W}}$  bit (the eighth bit). The  $\overline{R/\overline{W}}$  bit indicates the direction of data transfer—that is, whether data is being read from ( $\overline{R/\overline{W}} = 1$ ) or written to ( $\overline{R/\overline{W}} = 0$ ) the slave device. If the transmitted slave address matches the address of the device (set by the state of the  $A_0$  input pin; see Table 46), the [AD9888](#) acknowledges this by bringing SDA low on the ninth SCL pulse. If the addresses do not match, the [AD9888](#) does not send an acknowledgment.

**Table 46. Serial Port Addresses**

Bit 7 (MSB)	Bit 6	Bit 5	Bit 4	Bit 3	Bit 2	Bit 1
$A_6$	$A_5$	$A_4$	$A_3$	$A_2$	$A_1$	$A_0$
1	0	0	1	1	0	0
1	0	0	1	1	0	1

Figure 26. Serial Interface—Typical Byte Transfer

## DATA TRANSFER VIA SERIAL INTERFACE

For each byte of data read or written, the MSB is the first bit of the sequence.

If the [AD9888](#) does not acknowledge the master device during a write sequence, the SDA remains high so that the master can generate a stop signal. If the master device does not acknowledge the [AD9888](#) during a read sequence, the [AD9888](#) interprets this as being the end of data. The SDA remains high so that the master can generate a stop signal.

Writing data to a control register of the [AD9888](#) requires writing to its 8-bit address after the slave address is established. This control register address is the base address for subsequent write operations. The base address autoincrements by 1 for each byte of data written after the data byte intended for the base address. If more bytes are transferred than there are available addresses, the address does not increment and remains at its maximum value of 0x19. Any base address higher than 0x19 does not produce an acknowledge signal.

Data are read from the control registers of the [AD9888](#) in a similar manner. Reading requires two data transfer operations.

The base address must be written with the  $\overline{R/\overline{W}}$  bit of the slave address byte low to set up a sequential read operation.

Reading (with the  $\overline{R/\overline{W}}$  bit of the slave address byte high) begins at the previously established base address. The address of the read register autoincrements after each byte is transferred.

To terminate a read/write sequence to the [AD9888](#), a stop signal must be sent. A stop signal comprises a low-to-high transition of SDA while SCL is high.

A repeated start signal occurs when the master device driving the serial interface generates a start signal without first generating a stop signal to terminate the current communication. This is used to change the mode of communication (read or write) between the slave and master without releasing the serial interface lines.

### Serial Interface Read/Write Examples

#### Write to One Control Register

1. Start signal
2. Slave address byte ( $\overline{R/\overline{W}}$  bit = low)
3. Base address byte
4. Data byte to base address
5. Stop signal

#### Write to Four Consecutive Control Registers

1. Start signal
2. Slave address byte ( $\overline{R/\overline{W}}$  bit = low)
3. Base address byte
4. Data byte to base address
5. Data byte to (base address + 1)
6. Data byte to (base address + 2)

7. Data byte to (base address + 3)
8. Stop signal

**Read from One Control Register**

1. Start signal
2. Slave address byte ( $\overline{R/\overline{W}}$  bit = low)
3. Base address byte
4. Start signal
5. Slave address byte ( $\overline{R/\overline{W}}$  bit = high)
6. Data byte from base address
7. Stop signal

**Read from Four Consecutive Control Registers**

1. Start signal
2. Slave address byte ( $\overline{R/\overline{W}}$  bit = low)
3. Base address byte
4. Start signal
5. Slave address byte ( $\overline{R/\overline{W}}$  bit = high)
6. Data byte from base address
7. Data byte from (base address + 1)
8. Data byte from (base address + 2)
9. Data byte from (base address + 3)
10. Stop signal

**SYNC PROCESSING**

Figure 27 shows the sync processing block diagram, and Table 47 provides information related to serial register controls.

**Table 47. Control of the Sync Block Muxes via the Serial Register**

Mux Number(s)	Serial Bus Control Bit	Control Bit State	Result
1 and 2	0x0E, Bit 3	0	Pass HSYNC signal
		1	Pass sync-on-green signal
3	0x0F, Bit 5	0	Pass coast signal
		1	Pass VSYNC signal
4	0x0E, Bit 0	0	Pass VSYNC signal
		1	Pass sync separator signal
5	0x15, Bit 3	0	Pass Channel 0 inputs
		1	Pass Channel 1 inputs

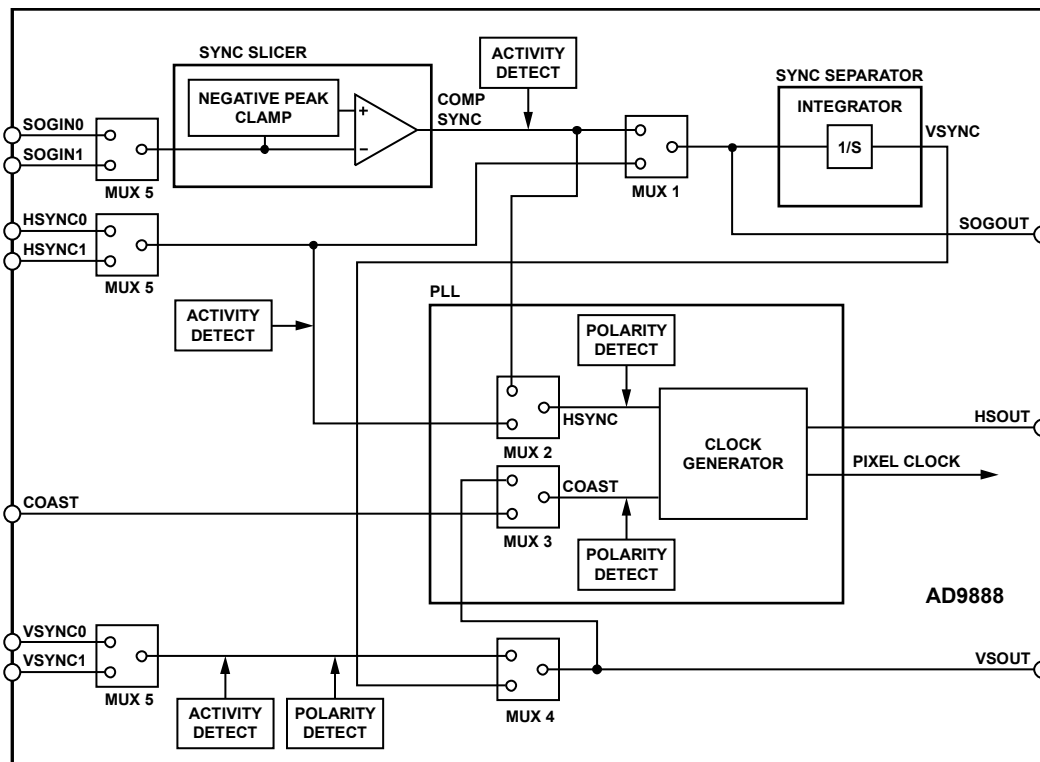

Figure 27. Sync Processing Block Diagram

### SYNC SLICER

The purpose of the sync slicer is to extract the sync signal from the green graphics channel. A sync signal is not present on all graphics signals, only those with sync-on-green. The sync signal is extracted from the green channel in a two-step process. First, the SOG input is clamped to its negative peak (typically 0.3 V below the black level). Next, the signal goes to a comparator with a variable trigger level, nominally 0.15 V above the clamped level. The “sliced” sync is typically a composite sync signal containing both HSYNC and VSYNC.

### SYNC SEPARATOR

A sync separator extracts the VSYNC signal from a composite sync signal by using a low-pass filter-like or integrator-like operation. It works on the idea that the VSYNC signal stays active for a much longer time than the HSYNC signal. Therefore, the sync separator rejects any signal shorter than a threshold value, which is somewhere between an HSYNC pulse width and a VSYNC pulse width.

The sync separator on the [AD9888](#) is an 8-bit digital counter with a 5 MHz clock. It works independently of the polarity of the composite sync signal. Polarities are determined elsewhere on the chip. The basic idea is that the counter counts up when

HSYNC pulses are present. Because HSYNC pulses are relatively short in width, the counter only reaches a value of N before the pulse ends. It then starts counting down, eventually reaching 0 before the next HSYNC pulse arrives. The specific value of N varies among video modes, but is always less than 255. For example, with a 1  $\mu$ s width HSYNC, the counter reaches only 5 ( $1 \mu\text{s}/200 \text{ ns} = 5$ ). When VSYNC is present on the composite sync, the counter also counts up. However, because the VSYNC signal is much longer, the counter reaches a higher number, M. For most video modes, M is at least 255. Therefore, VSYNC can be detected on the composite sync signal by detecting when the counter counts to higher than N. The specific count that triggers detection (T) can be programmed through the serial register (Address 0x0F).

After VSYNC is detected, there is a similar process to detect when it becomes inactive. Upon detection, the counter first resets to 0, and then starts counting up when VSYNC disappears. Similar to the previous case, the sync separator detects the absence of VSYNC when the counter reaches the threshold count (T). In this way, the sync separator rejects noise and/or serration pulses. After VSYNC is detected to be absent, the counter resets to 0 and begins the cycle again.

## PCB LAYOUT RECOMMENDATIONS

The AD9888 is a high precision, high speed analog device. To optimize its performance, it is important to have a well laid out board. This section provides guidelines for designing a board using the AD9888.

### ANALOG INTERFACE INPUTS

Using the following layout techniques on the graphics inputs is extremely important.

Minimize the trace length running into the graphics inputs by placing the AD9888 as close as possible to the graphics (VGA) connector. Long input trace lengths are undesirable because they pick up more noise from the board and other external sources.

Place the 75  $\Omega$  termination resistors (see Figure 4) as close as possible to the AD9888 chip. Any additional trace length between the termination resistors and the input of the AD9888 increases the magnitude of reflections, which corrupts the graphics signal.

Use 75  $\Omega$  matched impedance traces. Trace impedances other than 75  $\Omega$  increase the chance of reflections.

The AD9888 has very high input bandwidth (500 MHz). Although this is desirable for acquiring a high resolution PC graphics signal with fast edges, it means that the device also captures any high frequency noise present. Therefore, it is important to reduce the amount of noise coupled to the inputs. Avoid running any digital traces near the analog inputs.

The AD9888 can digitize graphics signals over a very wide range of frequencies (10 MHz to 170 MHz). Often, characteristics that are beneficial at one frequency can be detrimental at another. Analog bandwidth is one such characteristic. For UXGA resolutions (up to 170 MHz), a very high analog bandwidth is desirable because of the fast input signal slew rates. For VGA and lower resolutions (down to 12.5 MHz), a very high bandwidth is not desirable because it allows excess noise to pass through. To accommodate these varying needs, the AD9888 includes variable analog bandwidth control. Four settings are available (75 MHz, 150 MHz, 300 MHz, and 500 MHz), allowing the analog bandwidth to be matched with the resolution of the incoming graphics signal.

### POWER SUPPLY BYPASSING

It is recommended to bypass each power supply pin with a 0.1  $\mu\text{F}$  capacitor. The exception is when two or more supply pins are adjacent to each other. For these groupings of powers/grounds, it is necessary to have only one bypass capacitor. The fundamental idea is to have a bypass capacitor within about 0.5 cm of each power pin. In addition, avoid placing the capacitor on the side of the PC board opposite from the AD9888 because this interposes resistive vias in the path.

The bypass capacitors should be physically located between the power plane and the power pin. Current should flow from the power plane to the capacitor to the power pin. Do not make the power connection between the capacitor and the power pin.

Placing a via underneath the capacitor pads, down to the power plane, is generally the best approach.

It is particularly important to maintain low noise and good stability of  $\text{PV}_\text{D}$  (the PLL, VCO supply). Abrupt changes in  $\text{PV}_\text{D}$  can result in similarly abrupt changes in sampling clock phase and frequency. This can be avoided by careful regulation, filtering, and bypassing. It is highly desirable to provide separate, regulated supplies for each of the analog circuitry groups,  $\text{V}_\text{D}$  and  $\text{PV}_\text{D}$ .

Some graphics controllers use substantially different levels of power when active (during active picture time) and when idle (during horizontal and vertical sync periods). This can result in a measurable change in the voltage supplied to the analog supply regulator, which can in turn produce changes in the regulated analog supply voltage. This can be mitigated by regulating the analog supply, or at least  $\text{PV}_\text{D}$ , from a different, cleaner power source, for example, from a 12 V supply.

It is also recommended to use a single ground plane for the entire board. Experience shows that the noise performance is the same or better with a single ground plane. Using multiple ground planes can be detrimental because each separate ground plane is smaller, and long ground loops can result.

In some cases, using separate ground planes is unavoidable. For these cases, it is recommended to at least place a single ground plane under the AD9888. The location of the split should be at the receiver of the digital outputs, making it even more important to place components wisely because the current loops will be much longer, and current takes the path of least resistance. The following is an example of a current loop signal path: power plane to AD9888 to digital output trace to digital data receiver to digital ground plane to analog ground plane.

### PLL

Place the PLL loop filter components as close as possible to the FILT pin. Do not place any digital or other high frequency trace near these components. Use the values suggested in the data sheet with 10% tolerances or less.

### OUTPUTS (BOTH DATA AND CLOCKS)

Try to minimize the trace length that the digital outputs must drive. Longer traces have higher capacitance, requiring more current and causing more internal digital noise. Shorter traces reduce the possibility of reflections.

Adding a series resistor with a value of 22  $\Omega$  to 100  $\Omega$  can suppress reflections, reduce EMI, and reduce the current spikes inside the AD9888. However, if 50  $\Omega$  traces are used on the PCB, the data output should not need these resistors.

A 22  $\Omega$  resistor on the DATAACK output should provide good impedance matching that reduces reflections. If series resistors are used, place them as close as possible to the AD9888 pins, but avoid adding vias or extra length to the output trace.

If possible, limit the capacitance that each of the digital outputs drives to less than 10 pF. This can easily be accomplished by keeping traces short and connecting the outputs to only one device. Loading the outputs with excessive capacitance increases the current transients inside of the [AD9888](#), creating more digital noise on its power supplies.

### DIGITAL INPUTS

The digital inputs on the [AD9888](#) were designed to work with 3.3 V signals, but are tolerant of 5.0 V signals. Therefore, no extra components are needed when using 5.0 V logic.

Any noise in the HSYNC input trace produces jitter in the system. Therefore, minimize the trace length, and do not run any digital or other high frequency trace near it.

### VOLTAGE REFERENCE

The voltage reference should be bypassed with a 0.1  $\mu$ F capacitor. Place it as close as possible to the REF BYPASS pin. Make the ground connection as short as possible.

OUTLINE DIMENSIONS
